I. INTRODUCTION

Fermi-liquid (FL) theory, indispensable for our understanding of the low temperature properties of metals, predicts the electrical resistivity $\rho \sim T^2$, heat capacity $C \sim T$ and magnetic susceptibility $\chi$ independent of temperature $T$. The essence of Fermi-liquid theory is the quasiparticle concept introduced by Landau [1] which is an established paradigm of modern condensed matter physics. Metals with diverse physical properties have been found to follow the FL theory, including even unusual ones like heavy fermion systems, with a very large renormalized effective quasiparticle mass. Nevertheless, there remains a class of materials whose strange low temperature properties such as $\rho \sim T^n$ ($1 \leq n < 2$), $C/T \sim -\ln T$ or $C/T \sim a - bT^{1/2}$ and $\chi \sim -\ln T$ or $\chi \sim T^{-p}$ ($p < 1$). The presence of energy-temperature $E/T$ scaling in their dynamical spin susceptibility, with an anomalous exponent ($\alpha$), is another remarkable feature of some of the NFL systems that is characteristic of a strongly interacting quantum critical point [7]. Despite continuous efforts over the past two decades, the microscopic origin for the emergence of a NFL ground state is still not well understood. The single-ion multi-channel Kondo effect, proximity to a $T = 0$ K continuous quantum phase transition (QCP), and the Kondo disorder model are among the proposed theoretical models for NFL [3, 8–12]. The NFL behavior at a QCP is usually described by two theoretical scenarios: the conventional spin-density-wave (SDW) model of quantum criticality and the unconventional critical Kondo destruction model of local quantum criticality [8–11]. A model based on the critical Fermi surface has also been proposed for NFL behavior at a QCP [13]. The $E/T$ scaling of the dynamical susceptibility holds only for the unconventional critical Kondo destruction model of local quantum criticality as shown for CeCu$_{5.9}$Au$_{0.1}$ [14], in contrast to the Gaussian fixed point of the $T = 0$ SDW transition, where $E/T$ scaling is violated [15–17].

A QCP is usually accomplished by a non-thermal control parameter such as chemical composition, magnetic field or pressure that controls the amplitude of quantum...
fluctuations. Until recently most studies of NFL systems have been made on off-stoichiometric systems [3] in which the proximity to a QCP is accessed by tuning the chemical composition. However, the presence of inherent disorder in such systems makes it difficult to understand the individual roles of disorder and quantum criticality in producing NFL. Therefore, investigations on clean stoichiometric NFL systems are very important for a better and comprehensive understanding of the origin of the NFL behavior and a direct comparison with the theoretical predictions. Field-tuned YbRh$_2$Si$_2$ is one such stoichiometric quantum critical NFL system that has been a prototypical system for intensive study, yielding results consistent with the critical Kondo destruction scenario [18–22]. The observation of NFL behavior in stoichiometric systems usually requires tuning. The stoichiometric heavy fermion superconductor β-YbAlB$_4$ has recently been identified to show NFL features without any external tuning, the nature of quantum criticality in this material is still not clear [23–26]. The experimental realization of NFL behavior in a stoichiometric material, that is consistent with local quantum criticality, both without magnetic field and at ambient pressure has been challenging.

Here we present a stoichiometric system, namely the Kondo lattice heavy fermion compound CeRhBi that exhibits non-Fermi liquid behavior [27] without any tuning and thus is an ideal system for in-depth study using a wide range of microscopic techniques without the constraints on account of tuning by field or pressure. The nuclear quadrupole resonance study revealed no magnetic ordering down to 0.15 K, suggesting CeRhBi to be located close to a quantum critical point (on non-magnetic side) [28]. In order to understand the physics of NFL behavior in stoichiometric CeRhBi we have investigated the spin dynamics using inelastic neutron scattering (INS) and muon spin relaxation ($\mu$SR) techniques accessing a wide dynamic range. We find clear evidence of quantum critical scaling in the dynamic response of the INS and $\mu$SR asymmetry function, strongly indicating that the NFL behavior in this material originates from quantum criticality. Our results establish the stoichiometric CeRhBi to be an indispensable Ce-system in which a NFL behavior of local quantum critical origin is realized (through $E/T$ scaling of the dynamical susceptibility) without any tuning.

II. EXPERIMENTAL

Approximately 15 g polycrystalline samples of CeRhBi and its nonmagnetic reference compound LaRhSb were synthesized by melting the high purity elements in a sealed tungsten crucible and subsequent annealing at 900 °C for a week. The magnetic measurements were performed using a commercial superconducting quantum interference device magnetometer (MPMS, Quantum Design Inc.). The heat capacity and electrical resistivity were measured using a physical properties measurement system (PPMS, Quantum Design Inc.). The low energy inelastic neutron scattering measurements were carried out on the IN6 time-of-flight spectrometer using an incident energy $E_i = 3.1$ meV at ILL, Grenoble, France. The energy resolution at the elastic position was 0.08 meV. The high energy inelastic neutron scattering measurements were carried out on the HET time-of-flight spectrometer using $E_i = 60$ meV at the ISIS pulsed neutron and muon facility of the Rutherford Appleton Laboratory, Didcot, U.K. The $\mu$SR measurements were carried out on the MuSR spectrometer at ISIS. For the $\mu$SR measurement the powdered sample of CeRhBi was mounted on a high purity silver holder using GE varnish.

III. EVIDENCE FOR NON-FERMI LIQUID BEHAVIOR

Clear evidence of non-Fermi liquid behavior is seen from the temperature dependence of the electrical resistivity, heat capacity and magnetic susceptibility of CeRhBi shown in Fig. 1. While at high-temperature $\rho(T)$ exhibits a Kondo-lattice type feature [Fig. 1(a)], the low-$T$ $\rho(T)$ exhibits a T-linear behavior for 0.4 $\leq T \leq$ 3 K, i.e. $\rho(T) \sim T^n$ with $n = 1$ [Fig. 1(b)], a characteristic feature of non-Fermi liquid behavior. This NFL behavior is further supported by a logarithmic divergence in the magnetic heat capacity below 7 K, $C_M(T)/T \sim -\ln(T)$ for 0.7 $\leq T \leq$ 7 K [Fig. 1(c)] with a very large electronic
Sommerfeld coefficient $\gamma = C_M / T \approx 540$ mJ/mol K$^2$ at 0.7 K. Furthermore, the low-T $\chi(T)$ exhibits a power-law behavior below 20 K, $\chi(T) \sim T^{-p}$ with $p = 0.28$ [Fig. 1(d)]. Such a power-law divergence in magnetic susceptibility is predicted theoretically for a system near a locally critical quantum phase transition [8]. The broad peak in $\rho(T)$ near 100 K is due to the combined effect of Kondo effect and crystal field and the drop below 10 K is due to an onset of coherence. All these macroscopic properties reflect a local quantum critical behavior in CeRhBi, and motivated us to carry out inelastic neutron scattering measurements and examine the critical scaling of the spin dynamics.

IV. LOW ENERGY INELASTIC NEUTRON SCATTERING: $E/T$ SCALING

Figure 2(a) shows the color coded contour plot of the observed scattering from CeRhBi at $T = 1.8$ K measured on the neutron spectrometer IN6 at ILL, Grenoble, with incident energy $E_i = 3.1$ meV, plotted as energy transfer ($E$) versus momentum transfer ($Q$), revealing a clear sign of quasi-elastic scattering. Figure 2(b) shows the $Q$-integrated ($0 < Q < 2$ Å$^{-1}$) scattering intensity $S(Q, \omega)$ versus $E$ at different temperatures. (d) A log-log plot of $S(Q, \omega)$ data in (b) on the energy-loss part. The solid line shows $S(Q, \omega) \sim \omega^{-0.58}$ scaling behavior. (e) Dynamic susceptibility $\chi''(\omega, T)$ plotted as $\chi''(\omega, T)T^\alpha$ versus $E/T$ for $\alpha = 0.58$. The solid curve is the fit according to Aronson scaling function in Eq.(2). The inset in (e) shows the plot of goodness of the scaling analysis $\chi_{good}^2$ versus $\alpha$ obtained from the independent scaling analysis theory [38].

According to the fluctuation-dissipation theorem, the measured scattering intensity $S(Q, \omega, T)$ is related to the imaginary part of the dynamic susceptibility $\chi''(Q, \omega, T)$, [30]

$$S(Q, \omega, T) = \frac{\hbar}{\pi g^2 \mu_B^2} \frac{\chi''(Q, \omega, T)}{1 - \exp(-\hbar \omega / k_B T)}$$

(1)

with $\chi''(Q, \omega, T) = \omega F^2(Q) \chi'(0, 0, T) P(Q, \omega, T)$ according to the Kramers-Kronig relation, where $F(Q)$ is the magnetic form factor, $\chi'(0, 0, T) = \chi_0(T)$ is the static bulk susceptibility and $P(Q, \omega, T)$ is the normalized spectral function.

A double logarithmic plot of the magnetic scattering $S(Q, \omega, T)$ as a function of $E$ is shown in Fig. 2(d) for all the measured temperatures. The $S(Q, \omega, T)$ between 0.25 and 2 meV at all temperatures are linear in $E$ on a log-log scale suggesting a power law behavior. The magnetic scattering thus follows a scaling behavior, $S(Q, \omega, T) \sim \omega^{-\alpha}$ with $\alpha = 0.58$ ($\omega$ is re-
lated to $E$ by $E = \hbar \omega$). A very similar scaling behavior has also been observed in other non Fermi liquid systems such as UCo$_{5-x}$Pd$_x$ [31], CeRh$_{0.8}$Pd$_{0.2}$Sb [32], Ce$_{0.7}$Th$_{0.3}$RhSb [33] and CePd$_{0.15}$Rh$_{0.85}$ [34] with the exponent $\alpha = 0.33, 0.77, 0.33$ and 0.6, respectively.

Further, we find a clear evidence of $E/T$ scaling in the imaginary part of the dynamic susceptibility. The $\chi''(\omega, T)$ obtained is shown in Fig. 2(e) as $\chi''(\omega, T)T^\alpha$ versus $E/T$ plot. The $\chi''(\omega, T)$ data between 0.2 and 2 meV at $1.8 < T < 300$ K collapse onto a single curve. This confirms the universal $E/T$ scaling behavior of $\chi''(\omega, T)$. The $\chi''(\omega, T)$ data are well described by the scaling relation $\chi''(\omega, T)T^\alpha \sim f(\omega/T)$ with $\alpha = 0.58$. The solid curve in Fig. 2(e) represents the scaling function proposed by Aronson et al [31].

$$\chi''(\omega, T)T^\alpha = (T/\omega)^\alpha \tanh(\omega/\beta T)$$

for $\alpha = 0.58$ and $\beta = 0.5$. The $E/T$ scaling behavior has been observed in several NFL systems, however with different values of $\alpha$, and sometimes with different choice of scaling function $f(\omega/T)$. In quantum spin glasses UCo$_{5-x}$Pd$_x$ [31] and Sc$_{1-x}$U$_x$Pd$_3$ [35] $\alpha = 1/3$ and 0.2, respectively. In antiferromagnetic QCP systems CeCu$_{6-x}$Au$_x$ [36], CeRh$_{0.8}$Pd$_{0.2}$Sb [32], Ce$_{0.7}$Th$_{0.3}$RhSb [33] and Ce$_2$Pd$_4$ [37] $\alpha = 0.75, 0.77, 0.33$ and 1.5, respectively. In the ferromagnetic QCP system CeRh$_{0.85}$Pd$_{0.15}$ [34] $\alpha = 0.6$. The reason for the different values of the exponent in different compounds is not well understood. The wide variation in the $\alpha$ value might have a relation with the different origin to the quantum criticality, distance from the QCP in the phase space and the dimensionality including the amount of chemical disorder.

In order to further confirm the value of $\alpha$ from our analysis, we used a model free analysis method [38] that allows to estimate the goodness of the scaling $\chi_{\text{good}}^2$ versus $\alpha$ from the INS data in Fig. 2(b). The plot of $\chi_{\text{good}}^2$ versus $\alpha$ shown in the inset of Fig.2(e) gives $\alpha = 0.58(8)$ for a minimum value of $\chi_{\text{good}}^2$ validating our $E/T$ scaling analysis. The value of our exponent estimated from $E/T$ scaling (0.58) is close the theoretical value 0.72 predicted by a model based on a local QCP in an anisotropic Kondo lattice [39]. The scaling exponent should be the same in the dc-susceptibility and that obtained from $E/T$ scaling of the neutron data. The reason for the difference between the values of exponents obtained from the power-law behavior of $\chi(T)$ and $E/T$ scaling is not clear. The presence of magnetic anisotropy can lead to a preferred orientation in the dc-susceptibility data and hence a different exponent for the dc-susceptibility, however our crystal field model (approximated to a trigonal point symmetry of the Ce ion discussed below) does not show a clear evidence for such an anisotropy. The single crystal susceptibility of NFL CeRh$_2$Ga has been found to show two different values of the scaling exponents in the single crystal susceptibility, $\chi_\parallel \sim T^{-0.48}$ (for $H||c$-axis) and $\chi_\perp \sim T^{-0.79}$ (for $H\perp c$-axis) [40]. Nevertheless, the single crystal susceptibility data of CeRhBi would be enlightening.

We see that the $E/T$ scaling in neutron scattering is observed over a wide temperature range of 1.8 K to 300 K in contrast to the NFL behavior in bulk properties measurements at temperatures below 7 K (see Fig. 1). From the generic phase diagram of a quantum critical system [7] it is perceived that at a critical point the quantum fluctuations persist up to much higher temperatures (there is no sharp cut-off in temperature, it is the relative strength of quantum and thermal fluctuations which is important for a non-Fermi liquid behavior). Because of the persistent quantum fluctuations, the temperature range for observation of NFL behavior may depend on the measurement techniques and their probing time. The $E/T$ scaling of the neutron scattering results, which measures the dynamical response or spin-spin correlations, is commonly observed up to much higher temperatures, which is because of the wide spatial and temporal range of probing time- and length-scales of neutron technique that can detect the spin-spin correlations even up to 300 K. We believe that it can be justified because the Kondo crossover is slow and extends over a very large temperature and energy ranges.

V. HIGH ENERGY INELASTIC NEUTRON SCATTERING: CRYSTAL FIELD STATES

The INS data measured with high incident energy neutrons show evidence for crystal field excitations within the $J = 5/2$ ground multiplet of Ce$^{3+}$. From the $Q$-dependence of magnetic form factor squared $[F^2(Q)]$ indicating that at high incident energies the inelastic excitations in CeRhBi result essentially from the single-ion CEF transitions. The magnetic scattering intensity $S(Q, \omega)$ versus $E$ at 5 K obtained from HET data is shown in Fig. 3(b). We analyze these high energy INS data by a model based on crystal field. The crystal field is expected to remove the six-fold degeneracy of ground state of Ce$^{3+}$ ($^2F_{5/2}$) splitting it into three doublets. Therefore one would expect two CEF excitations from the two excited states, how-
ever $S(Q, \omega)$ in Fig. 3(b) shows only a rather broad CEF excitation (near 30 meV) which could be due to two unresolved excitations because of a very small splitting energy between the two excited states. CeRhBi forms in TiNiSi-type orthorhombic structure (space group $Pnma$, No. 62). In this orthorhombic structure CeRhBi has a triclinic point symmetry which can be approximated to a trigonal $D_{3d}$ symmetry such that the CEF Hamiltonian can be described as

$$H_{CEF} = B_0^m O_m^0 + B_4^m O_4^m + B_4^3 O_4^3$$  \hspace{1cm} (3)$$

where $O^m_n$ are the Stevens’ equivalent operators and $B^m_n$ are phenomenological CEF parameters. The red solid curve in Fig. 3(b) represents the fit to this CEF model. Also shown are the different components of the fit. The CEF analysis of INS data yield the phenomenological parameters (in meV) $B_0^2 = -0.0156$, $B_4^0 = -0.0479$, and $B_4^3 = -1.648$ and splitting of the three doublets to be 0, 28.68 and 31.38 meV. The ground state wave function is a mixture of $|\pm 1/2\rangle$ and $|\pm 5/2\rangle$.

![Figure 3](image_url)

**FIG. 3.** (Color online) (a) Magnetic inelastic neutron scattering response, a color-coded map of the intensity, energy transfer ($E$) versus momentum transfer ($Q$) of CeRhBi measured with the incident energy $E_i = 60$ meV at 5 K using the HET spectrometer at ISIS. (b) The magnetic scattering intensity $S(Q, \omega)$ versus $E$ at 5 K. Solid red curve is the fit based on the crystal field model. The dashed and dash-dotted lines represent the different components of fit.

Figure 4 shows a comparison of the crystal field susceptibility $\chi_{CEF}(T)$ obtained using the above CEF model with the experimental susceptibility. The experimental susceptibility is reasonably well represented by $\chi(T)^{-1} = \chi_{CEF}(T)^{-1} - \lambda_m$, where $\lambda_m$ is the molecular field constant. The red solid curve in Fig. 4 represents CEF susceptibility along with $\lambda_m = 76(3)$ mol/emu. The reasonable agreement between the $\chi(T)$ and $\chi_{CEF}(T)$ supports the validity of proposed CEF model. The inset in Fig. 4 shows the $\chi_{CEF}(T)$ along the three crystallographic directions using the CEF parameters obtained from the INS fit.

**VI. MUON SPIN RELAXATION: TIME-FIELD SCALING**

The representative $\mu$SR spectra collected at various temperatures between 50 mK and 4 K while warming the sample in zero field (ZF) are shown in Fig. 5(a). The absence of frequency oscillations or any loss in initial asymmetry indicates no long range order down to 50 mK, though the muon depolarization rate seems to increase as the temperature is lowered indicating that the muons sense the presence of quantum fluctuations. The ZF $\mu$SR spectra are well described by a Gaussian Kubo-Toyabe function multiplied by an exponential de-
FIG. 5. (Color online) (a) The zero field μSR spectra collected at the indicated temperatures. The solid curves are the fits to the data by Eq. (4). (b) The longitudinal field μSR spectra collected at indicated fields at 50 mK. The solid curves are the fits to the data by Eq. (6). (c) Time-field scaling of longitudinal field μSR data in (b), $G_z(t)$ versus $t/H^0$ for $\eta = 0.80$. (d) Temperature $T$ dependence of the depolarization rate $\lambda$ obtained from the zero field μSR data. (e) $T \ln(\lambda)$ versus $T$ plot. The solid line is the fit according to Arrhenius-like activated behavior. (f) Field $H$ dependence of $\lambda$ obtained from the longitudinal field μSR data. The solid curve is the fit according to Eq. (7).

cay,

$$G_z(t) = A_0 \left[ \frac{1}{3} + \frac{2}{3} \left( 1 - \sigma^2 t^2 \right) e^{-\sigma^2 t^2/2} \right] e^{-\lambda t} + A_{BG} \quad (4)$$

where $A_0$ is the initial asymmetry from the sample and $A_{BG}$ is the asymmetry contribution from the silver sample holder, $\sigma$ is the relaxation rate of the Gaussian channel of depolarization which provides a measure of the distribution of static magnetic fields at the muon site arising from the nuclear moments that are static on the time scale of the muon lifetime, and $\lambda$ is the relaxation rate of the Lorentzian channel accounting for the dynamic magnetic fields due to fluctuating electronic moments. The fits of the ZF μSR spectra by Eq. (4) are shown by the solid curves in Fig. 5(a). The fit parameter $\sigma$ was found to be constant within the error bar therefore for final fits we fixed it to $\sigma = 0.0735 \mu$s$^{-1}$. $A_0$ was also found to remain fairly $T$-independent with a value of about 0.20, however a sharp increase is seen in $\lambda(T)$ as $T$ decreases [Fig. 5(d)].

$\lambda$ is related to the spin-fluctuation rate $\nu$ according to the Redfield equation [41]

$$\lambda \sim \frac{2 \gamma_\mu^2 \langle H^2_{loc} \rangle \nu}{\nu^2 + \gamma_\mu^2 H^2} \quad (5)$$

where $\langle H^2_{loc} \rangle$ is the time average of the second moment of the time-varying local field $H_{loc}(t)$ at muon sites due to the fluctuations of neighboring Ce 4f moments, and $H$ is the applied magnetic field. According to Eq. (5), in the absence of applied field $H = 0$, therefore at zero field $\lambda \sim 1/\nu$, i.e., $\lambda$ is inversely proportional to the spin-fluctuation rate. Thus an increase in $\lambda$ (with decreasing temperature) indicates a decrease in spin-fluctuation rate and hence a slowing down of dynamic spins.

The $\lambda(T)$ diverges as $T \to 0$ K, and shows an activated behavior $\lambda(T) = \lambda_0 \exp(E_g/k_B T)$ or equivalently $T \ln(\lambda) = T \ln(\lambda_0) + E_g/k_B$, where $E_g$ is the energy gap and $k_B$ is the Boltzmann’s constant. A linear fit of $T \ln(\lambda)$ versus $T$ plot [Fig. 5(e)] yields $E_g = 0.14(3)$ K. Thus the spin dynamics seems to be thermally activated, indicating the presence of low energy spin fluctuations in CeRhBi. A very similar behavior was also observed for CeInPt$_4$ with activation energy of 2.9 mK [42].

The application of a longitudinal magnetic field is found to decouple the nuclear component such that the LF μSR spectra are well described by a simple Lorentzian function,

$$G_z(t) = A_0 e^{-\lambda t} + A_{BG}. \quad (6)$$

The LF μSR spectra collected at 50 mK for $5 \leq H \leq 250$ mT and fits to them (solid curves) are shown in
The $H$ dependence of the electronic relaxation $\lambda$ is shown in Fig. 5(f). The $\lambda$ initially decreases rapidly with increasing $H$ and eventually tends to be constant. The $\lambda(H)$ allows us to estimate the spin auto correlation time $\tau_c$ according to the fluctuation-dissipation theorem which relates $\tau_c(H)$ to the imaginary component of the local $Q$-independent $f$-electron dynamic susceptibility $\chi''(\omega)$, which for $h\omega \ll k_B T$ is given by

$$\tau_c(H) = (k_B T/\mu^2)\chi''(\omega)/\omega.$$  

The $\lambda(H)$ data follow [41]

$$\lambda(H) = \lambda_0 + \frac{2\gamma^2 \langle H^2_{\text{loc}} \rangle \tau_c}{1 + \frac{2\mu^2}{k_B^2 T^2} \tau_c^2} \quad (7)$$

where $\lambda_0$ is the $H$-independent depolarization rate, $\langle H^2_{\text{loc}} \rangle$ is the time average of the second moment of the time-varying local field $H_{\text{loc}}(t)$ at muon sites due to the fluctuations of neighboring Ce 4f moments. The fit of the $\lambda(H)$ by Eq. (7) obtained for $\lambda_0 = 0.17(1) \mu$s$^{-1}$, $\sqrt{\langle H^2_{\text{loc}} \rangle} = 1.5(1)$ mT, and $\tau_c = 4.2(6) \times 10^{-8}$ s is shown by the solid red curve in Fig. 5(f). The value of $\tau_c$ reveals a slow spin dynamics which is caused by the quantum critical fluctuations.

Furthermore we find that the LF $\mu$SR data follow characteristic time-field scaling $G_z(t, H) = G_z(t/H^n)$, where the exponent $n$ provides information about spin-spin dynamical autocorrelation, $n < 1$ for power-law correlation and $n > 1$ for stretched exponential correlation [43–45]. The $G_z(t)$ versus $t/H^n$ plot of $H$-dependent LF $\mu$SR data at $T = 50$ mK are shown in Fig. 5(c). The time-field scaling of $\mu$SR data at $T = 50$ mK is evident from Fig. 5(c) for $n = 0.80(5)$. The value of $n = 0.80(5) < 1$ suggests a power-law correlation and hence cooperative and critical spin fluctuations in CeRhBi. This kind of time-field scaling in LF $\mu$SR has been observed in a few other NFL systems [45], such as in UCu$_{6-x}$Pd$_x$ with $n = 0.35$ for $x = 1$ and $n = 0.7$ for $x = 1.5$ [44]. The stoichiometric antiferromagnetic QCP system YbRh$_2$Si$_2$ [46] shows time-field scaling with $n \approx 1$. The ferromagnetic QCP system CePd$_{0.15}$Rh$_{0.85}$ [47] shows scaling for $n = 1.0(1)$.

Because of the modification in muon relaxation by the application of field [Eq. (4) for ZF and Eq. (6) for LF data] we believe that a small activation energy in the ZF data does not have any significant bearing on the observed time-field scaling in LF data. In view of observed time-field scaling, it seems that the activated behavior seen in ZF $\lambda(T)$ very likely disappears in LF data, however this remains to be verified experimentally by LF measurements at a given field and several temperatures. We would like to point out that the lack of this information about the effect of field on activation behavior of $\lambda$ does not have any consequence on the results and conclusions reached in this paper. This has been also supported through the $\mu$SR study on the NFL system CePd$_{0.15}$Rh$_{0.85}$ [47], where LF data exhibits time-field scaling, but ZF-muon depolarization rate ($\lambda$) exhibits a power-law behavior. This suggests that the time-field scaling is a unique property of NFL systems.

VII. DISCUSSION AND SUMMARY

The linear $T$ dependence of $\rho$, logarithmic divergence of $C(T)/T$ and power-law divergence of $\chi(T)$ provide clear evidence of a NFL ground state in CeRhBi. Further, the INS data reveal universal $E/T$ scaling of $\chi''(\omega, T)$ and $\mu$SR spectra show the time-field scaling. While the time-field scaling indicates slowing of spin-dynamics due to quantum critical fluctuations, the $E/T$ scaling and power-law divergence of $\chi(T)$ provide strong evidence for local quantum criticality [8] in CeRhBi. Importantly, the quantum critical behavior is realized at zero field and ambient pressure. As there is no obvious inherent disorder in CeRhBi (being stoiiochimetric and crystallographically well ordered) the Kondo disorder model is of not much relevance here. Moreover, the multichannel Kondo effect model too is not relevant as the $\chi(T)$ does not follow the expected logarithmic divergence. In view of the local quantum criticality, the NFL behavior in CeRhBi seems to have its origin in a clean continuous quantum phase transition. Even though there is no obvious source of disorder (in terms of off-stoichiometry, chemical doping or site-mixing), the presence of disorder effect cannot be completely ruled out.

The theory of local quantum criticality [8, 9] was formulated to explain the origin of NFL behavior and $E/T$ scaling in CeCu$_{6-x}$Au$_x$ [14, 36, 48]. The local quantum criticality is associated with the breakdown of the Kondo screening, resulting in a collapse of the Fermi surface [11], however the off-stoichiometric nature of CeCu$_{6-x}$Au$_x$ limits a precise study of the Fermi surface in this material. Evidence for the critical destruction of Kondo screening (Fermi-surface collapse) has been found from Hall-effect measurements [21, 22] on the stoichiometric heavy fermion YbRh$_2$Si$_2$ that exhibits a magnetic field-tuned quantum criticality and NFL ground state [18–20]. A similar critical Kondo destruction has also been observed in field-tuned quantum critical heavy fermion system Ce$_3$Pd$_{20}$Si$_6$ [49]. Similar evidence has came from quantum-oscillation measurements of the Fermi surface in the heavy fermion CeRhIn$_5$ [50].

To summarize, our spin dynamics study of stoichiometric non-Fermi-liquid heavy fermion CeRhBi provides clear evidence for universal quantum critical scaling in this compound over a very wide dynamic range. CeRhBi thus emerges as a significant Kondo lattice system, situated at a quantum critical point at zero field and ambient pressure in stoichiometric form. That the unconventional local quantum criticality in CeRhBi is realized without any tuning makes it a promising system for comprehensive studies to unravel the puzzle of quantum criticality and NFL physics. Of particular interest will be to probe the Fermi surface using techniques such as angle-resolved photoemission spectroscopy (ARPES) and to examine the criticality of the Fermi surface. From a more general materials perspective, the critical Kondo destruction, which is the most favored underlying mechanism for the dynamical $E/T$ scaling, has so far been typi-

appendix a: crystal structure

Figure 6 shows the crystal structure of CeRhBi, which 
crystallizes in the orthorhombic TiNiSi-type structure 
with space group $Pnma$ (No. 62). The orthorhombic 
lattice parameters are $a = 7.431 \, \AA$, $b = 4.727 \, \AA$, 
and $c = 7.991 \, \AA$. The shorter distances for Ce-Ce are 
3.832, 3.8796 $\AA$, Ce-Rh are 3.1271, 3.2984 $\AA$ and Ce-
Bi are 3.1417, 3.3601 $\AA$. The Ce-atoms form a zig-zag 
chain along the b-axis. The crystal structure of CeR-

CeRhBi is same as that of Kondo insulators CeRhSb and 
CeNiSn and both of them are low-carrier-density Kondo 
insulators with enhanced spin fluctuation but no mag-
netic ordering down to 100 mK. Each cerium atom is 
surrounded by a polyhedron of twenty atoms, i.e. 8 Ce, 
6 Rh and 6 Bi atoms. The coordination numbers of Rh 
and Bi atoms are 10 and their coordination polyhedra 
are trigonal prisms. Generally, a distinguishing feature 
for the TiNiSi type compounds is the different coordina-
tion of the metal and nonmetal atoms.

Appendix B: Magnetic Susceptibility and 
Magnetization

Figure 7 shows the temperature $T$ dependence of magnetic susceptibility $\chi$ of CeRhBi measured at an 
applied field $H = 1.0 \, T$. At high temperature the 
$\chi(T)$ data follow Curie-Weiss behavior $\chi(T) = C/(T - \theta_p)$. 
A linear fit of the inverse susceptibility $\chi^{-1}(T)$ in 
$150 \leq T \leq 380 \, K$ yields the paramagnetic Weiss tem-
perature $\theta_p = -117(1) \, K$ and Curie constant $C = 
0.870(2) \, emu/mol K$ corresponding to an effective mag-
netic moment $\mu_{\text{eff}} = 2.64 \mu_B$. The $\mu_{\text{eff}}$ which is close 
to the theoretical value of $2.54 \mu_B$ expected for a free 
Ce$^{3+}$ ion, indicates a Ce$^{3+}$ state of Ce ions at high 
temperatures. The isothermal magnetization $M(H)$ data at 
$2 \, K$ are shown in the inset of Fig. 7. It is seen that 
the $M$ attains only about 0.1 $\mu_B$/Ce at 5.0 T which 
is much smaller than the expected saturation moment of 
$2.14 \mu_B$/Ce for Ce$^{3+}$ ion. The slight nonlinearity in 
$M(H)$ could be the result of the crystal electric field ef-
efect and/or Kondo coherence.
FIG. 8. (Color online) Heat capacity \( C/T \) versus temperature \( T \) on a semi-log scale to show the logarithmic divergence of coefficient \( \gamma \). The \( C(T) \) of LaRhBi [29] is also shown. The solid blue curve is the calculated \( C(T) \) for nonmagnetic reference LaRhBi according to Debye model of lattice heat capacity. The inset shows the magnetic entropy \( S_M(T) \).

Appendix C: Heat Capacity

Figure 8 shows the heat capacity \( C(T) \) of CeRhBi plotted as \( C/T \) versus \( T \) CeRhBi. The low-\( T \) \( C(T) \) data show a clear logarithmic divergence of Sommerfeld coefficient \( \gamma(T) = C(T)/T \sim -\ln(T) \) at \( T \leq 7.0 \) K. The magnetic contribution to heat capacity \( C_M \) was obtained by subtracting off the phonon contribution using the reported low temperature heat capacity of LaRhBi [29]. The low-\( T \) normal state \( C(T) \) of LaRhBi is well described by \( C(T) = \gamma T + \beta T^3 \) with \( \gamma = 190 \) mJ/mol K\(^2\) and \( \beta = 0.74 \) mJ/mol K\(^4\). A Debye temperature of \( \Theta_D = 199 \) K is obtained from the value of \( \beta \). In order to obtain the phonon contribution over an extended region of temperature we calculated Debye lattice heat capacity (blue curve in Fig. 8) according to [51]

\[
C_{V, \text{Debye}}(T) = 9nR \left( \frac{T}{\Theta_D} \right)^3 \int_0^{\Theta_D/T} \frac{x^4 e^x}{(e^x - 1)^2} \, dx, \quad (C1)
\]

for \( \Theta_D = 199 \) K, which was then subtracted off from \( C(T) \) of CeRhBi. The \( C_M(T) \) obtained this way is shown in Fig. 1(c) of manuscript. The magnetic entropy \( S_M(T) \) obtained from the \( C_M(T) \) data is shown in the inset of Fig. 8. From the magnetic entropy one can estimate Kondo temperature which is twice the temperature at which \( S_M = 0.4R \ln 2 \), accordingly we obtain \( T_K \approx 14 \) K.
